Abstract

Objective: Myotonic dystrophy type 1 (DM1) is caused by the expansion of a CTG repeat in the 3′ untranslated region of DMPK. The transcripts containing an expanded CUG repeat (CUGexp) result in a toxic gain-of-function by forming ribonuclear foci that sequester the alternative splicing factor muscleblind-like 1 (MBNL1). Although several small molecules reportedly ameliorate RNA toxicity, none are ready for clinical use because of the lack of safety data. Here, we undertook a drug-repositioning screen to identify a safe and effective small molecule for upcoming clinical trials of DM1. Methods: We examined the potency of small molecules in inhibiting the interaction between CUGexp and MBNL1 by in vitro sequestration and fluorescent titration assays. We studied the effect of lead compounds in DM1 model cells by evaluating foci reduction and splicing rescue. We also tested their effects on missplicing and myotonia in DM1 model mice. Results: Of the 20 FDA-approved small molecules tested, erythromycin showed the highest affinity to CUGexp and a capacity to inhibit its binding to MBNL1. Erythromycin decreased foci formation and rescued missplicing in DM1 model cells. Both systemic and oral administration of erythromycin in the DM1 model mice showed splicing reversal and improvement of myotonia with no toxicity. Long-term oral administration of erythromycin at the dose used in humans also improved the splicing abnormality in the DM1 model mice. Interpretation: Oral erythromycin treatment, which has been widely used in humans with excellent tolerability, may be a promising therapy for DM1.

Introduction

Myotonic dystrophy type 1 (DM1) is the most common type of muscular dystrophy in adults. This systemic disease presents with multiple symptoms, including myotonia, progressive muscle weakness, insulin resistance, cardiac conduction defects, and cognitive dysfunction. DM1 is caused by the expansion of a CTG repeat in a 3′ untranslated region, giving rise to toxic RNAs containing expanded CUG repeats.

in the nucleus, forming ribonuclear inclusions that sequester muscleblind-like (MBNL) family-member proteins. MBNL proteins are thought to play roles in the regulation of alternative splicing, mRNA localization, micro RNA processing, and alternative polyadenylation. Accordingly, MBNL1 sequestration in DM1 leads to misregulation of alternative splicing of muscle-specific chloride channel (CLCN1) and insulin receptor (INSR) RNAs, resulting in myotonia and glucose intolerance, respectively.

Several therapeutic approaches have been recently developed to ameliorate RNA toxicity in DM1 models. One approach involves the use of antisense oligonucleotides to directly degrade toxic RNAs or inhibit MBNL1 sequestration. The other approach is to modulate toxic RNAs with small molecules. Pentamidine and its derivatives reportedly decrease the production of toxic RNAs in DM1 mice. Several compounds, including aminoglycoside derivatives, are believed to block the binding between toxic RNAs and MBNL1. These small molecules neutralize toxic RNA and ameliorate splicing abnormalities to some extent. However, most of these compounds are not pharmaceuticals, and the safety of these compounds in humans is still unknown. Pentamidine is the only exception, being currently used to treat Pneumocystis carinii pneumonia. However, the dose of pentamidine required for effective splicing rescue in DM1 mice is much higher than that used for humans, and such high-dose treatment showed certain toxicity in mice. Thus, in spite of the present high demand for DM1 treatment, these small molecules remain far from clinical use. In addition, the time required to develop a new drug de novo is estimated to be >10 years because of regulatory requirements regarding safety, efficacy, and quality. A strategy to find new uses for existing drugs, known as “drug repositioning,” is now being used to bring drugs to more patients without delay. In this study, we conducted a drug-repositioning screen to identify potential therapeutic agents for treating DM1, and found that not only systemic delivery but also oral administration of erythromycin, a widely used antibiotic in humans, reduced RNA toxicity, and improved splicing abnormalities in DM1 model mice.

**Fluorescence titration assay**

Recording of emission spectra was carried out for fluorescently labeled (CUG)$_{10}$ RNA incubated with different concentrations of antibiotics. Five-nanomolar RNA (GGC–CUG)$_{10}$–GGC labeled at the 5′-end with Cy-3 (Future Synthesis, Poznan, Poland) was incubated at 37°C for 5 min with erythromycin lactobionate, streptomycin, and paramomycin of indicated concentrations (ranging from 0 to 100 μmol/L). The binding reaction was performed in a volume of 2 mL in 1× binding buffer (250-mmol/L NaCl, 15-mmol/L KCl, 50-mmol/L Tris–HCl, 1-mmol/L MgCl$_2$, pH 8.0). The emission spectra of RNA and RNA/antibiotic complexes were recorded using a spectrophotometer (UV1602; Shimadzu, Kyoto, Japan) at 520-nm excitation wavelength. Raw data were corrected for dilution-dependent changes, and Em$_{560}$ was plotted against antibiotic concentrations and fit to the one site-specific binding equation $y = (b_{max} \times x)/(K_d + x)$.

**Cell model**

Fibroblasts derived from DM1 patients (cell line GM03989 expressing a DMPK transcript with ~2000 CUG repeats) and control fibroblasts derived from non-DM1 patients (cell line GM07492) were purchased from the Coriell Cell Repositories (Camden, NJ). A conditional cell model for analysis of MBNL1 splicing regulatory activity has been established as reported previously. Briefly, C2C12 mouse muscle cells were co-transfected with pLC16 containing 800 CTG repeats and plasmid PhiC31o encoding PhiC31 integrase (Addgene, Cambridge, MA). Transfection was performed, using Nucleofector technology (Lonza, Basel, Switzerland) according to the manufacturer’s program B-32. Stably transfected clones were selected with puromycin (1.25 μg/mL). Transcription across the expanded repeat was activated by Cre recombinase-mediated excision of a transcription terminator cassette. C2C12 cells with recombination were selected, using hygromycin B (300 μg/mL). RNA was harvested after 2 days of incubation with erythromycin lactobionate.

**Treatment in mice**

Mouse handling and experimental procedures were performed in accordance with the Osaka University guidelines for the welfare of animals, and were approved by the institutional review board. Homozygous HSA12 transgenic mice of line 20b (FVB inbred background) have been described previously. Gender-matched and age-matched (<3 months old) mice were treated with phosphate-buffered saline (PBS) or erythromycin lactobionate or ethylsuccinate at the indicated dose and period by daily

intraperitoneal injection or oral administration. After the treatments, mice were sacrificed, and the rectus femoris (quadriceps) muscle was obtained for splicing analysis. At least six mice were used in each experimental group. Electromyography was performed under general anesthesia as described previously. Briefly, at least 10 needle insertions were performed in the vastus muscle, and myotonic discharges were graded on a four-point scale: 0, no myotonia; 1, occasional myotonic discharge in ≤50% of needle insertions; 2, myotonic discharge in >50% of insertions; and 3, myotonic discharge with nearly all insertions.

RNA extraction and splicing analysis

Total RNA extraction from model cells and mouse muscles, cDNA synthesis, and polymerase chain reaction (PCR) amplification were performed as described previously. The PCR products were separated by agarose gel electrophoresis, and the gel was stained with GelRed (Biotium, Hayward, CA). The gel was imaged using a Typhoon laser fluorimager (GE Healthcare, Pittsburgh, PA) and the products quantified using ImageQuant (GE Healthcare). Splicing analyses for DM1 and non-DM1 fibroblasts treated with erythromycin were performed as described previously. A two-tailed t-test was used to determine the statistical significance of differences between two groups.

mRNA quantification

Quantitative reverse transcriptase-PCR was performed, using TaqMan Gene Expression assays on an ABI PRISM 7900HT Sequence Detection System (Applied Biosystems, Carlsbad, CA). The level of endogenous mouse Dmpk, and transgene-derived mRNA was normalized to 18S rRNA or Gtf2b as described previously.

Fluorescence in situ hybridization

Fluorescence in situ hybridization (FISH) for C2C12 cells and DM1 fibroblasts was performed as previously described. Fluorescence images were obtained using an Olympus FV1000D confocal laser scanning microscope (Olympus, Tokyo, Japan). The number of foci was counted from at least 200 nuclei in two independent experiments.

Results

Drug-repositioning screen for DM1

Previous reports showed that small molecules can efficiently interrupt toxic RNA–MBNL interaction. Many of these compounds are antibiotics-like molecules with an ability to bind rRNA. Therefore, we screened 20 FDA-approved antibiotics that repress translation by binding RNA and are well characterized with respect to tolerability, safety, and toxicity for human use. To find potential inhibitors of interactions between toxic RNA and MBNLs, we first performed in vitro sequestration assays using surface-attached (CUG)100 RNA and labeled recombinant MBNL1 at three concentrations of each compound (Fig. S1). Of these compounds, neomycin and erythromycin showed significant inhibition of protein aggregation (up to 50%) at 10 and 50 μmol/L (Fig. S1). To confirm the initial screening results, we performed electrophoretic mobility shift assays (EMSA) with a higher range of concentrations of neomycin and erythromycin. A maximum of 50–60% reduction in (CUG)100 RNA molecules bound to MBNL1 was observed, with Kd being ~2–10 μmol/L (Fig. 1A). To determine whether an inhibition observed in two assays was caused by direct interaction between the antibiotics and RNA, we carried out the fluorescence titration assay for internal fluorescent-labeled (CUG)100 for selected compounds. Neomycin and erythromycin showed Kd < 1 μmol/L (streptomycin as a negative control with much higher Kd; data not shown). We then calculated Kd values using shorter 5′-Cy3-labeled (CUG)10 and found that erythromycin lactobionate showed the strongest fluorescence change with Kd = 0.78 μmol/L (Fig. 1B and C).

Validation in DM1 model cells

From our initial screen, we found that neomycin and erythromycin lactobionate effectively interrupted MBNL1 sequestration. However, neomycin is less used in humans because of its nephrotoxicity and ototoxicity and did not improve misregulated splicing in a previous study. Indeed, in our study, subcutaneous injection of neomycin into the DM1 model mice did not significantly improve splicing, even with a dosage equivalent to LD50 (100 mg/kg per day; data not shown). Therefore, we focused on erythromycin and investigated its effects on DM1 model cells. First, we used C2C12 murine myogenic cells that were stably transfected with a construct for conditional expression of (CUG)300 RNA. After induction of toxic RNA expression, these cells displayed ribonuclear foci (62.8% positive for nuclear foci) and showed a splicing abnormality in Atp2a1 (36.8% inclusion of exon 22) similar to that observed in DM1 (Fig. 2A and B). After 2 days of treatment with 25- or 50-μmol/L erythromycin, the frequency of cells showing nuclear foci decreased to 14.3% or 5.9%, respectively (Fig. 2A). The missplicing of Atp2a1 was mostly rescued by erythromycin in a dose-

nia and misregulated splicing. To test activity and exhibit several DM1-like characteristics, including myotonia, mice express 220 CUG repeats in skeletal muscle and cause myotonia. The wild-type adult mice had a skeletal muscle. Missplicing of Clcn1 and Atp2a1 and Clcn1 in injection for 8 days. Although the dosage of erythromycin was expected, the antibiotic did not perturb the splicing of several exons regulated by MBNLs (MBNL1 ex5, MBNL2 ex5, and NCOR2 ex45a) in cells treated with 50–100-μmol/L erythromycin, respectively, compared to untreated cells, which were half their size at most. We also observed significant correction of splicing of several exons regulated by MBNLs (MBNL1 ex5, MBNL2 ex5, and NCOR2 ex45a) in cells treated with 50–100-μmol/L erythromycin (Fig. 3). As was expected, the antibiotic did not perturb the splicing of MBNL-independent transcripts (APLP2 ex14 and KIF13A ex26) (Fig. 3C).

**In vivo treatment with erythromycin**

Next, we tested the effect of erythromycin on RNA toxicity in the HSA1LR transgenic DM1 mouse model. These mice express 220 CUG repeats in skeletal muscle and exhibit several DM1-like characteristics, including myotonia and misregulated splicing. To test activity and acute toxicity, we administrated erythromycin (150 mg/kg per day) to the HSA1LR mice by daily intraperitoneal (i.p.) injection for 8 days. Although the dosage of erythromycin was 2–3 times as much as used for humans, no mice showed signs of toxicity. We assessed splicing of Clcn1 and Atp2a1, both of which are regulated by MBNL1, in skeletal muscle. Missplicing of Clcn1 has been suggested to cause myotonia. The wild-type adult mice had a Clcn1 exon 7a exclusion rate of 94%, whereas the HSA1LR mice showed an exclusion rate of 57% (Fig. 4A). Treatment of the HSA1LR mice with i.p. erythromycin significantly rescued the exclusion rate to 83% (P = 0.000005). The splicing misregulation of Atp2a1 is also a robust biomarker for DM1. In the wild-type mice, the inclusion rate for exon 22 is 100%, whereas the inclusion rate in the HSA1LR mice was 31% (Fig. 4A). After erythromycin treatment, the inclusion rate improved significantly to 76% (P = 0.0000001). In addition to Clcn1 and Atp2a1, misregulation of other splicing events related to muscle wasting (Bin1 and Cacna1s), early transition (Cramk2b and Ryr1), and regulation by MBNL1 (Nfix and Ldb3) was rescued by systemic erythromycin treatment (Fig. S2). Furthermore, splicing misregulation of both Clcn1 and Atp2a1 was significantly improved by the dose usually used in humans (50 mg/kg per day for 8 days; P = 0.003 and 0.004, respectively). We also graded the severity of myotonia in mice using electromyography. In the HSA1LR mice treated with saline, we observed grade 3 myotonia in the vastus muscle, indicating abundant repetitive discharges with nearly all electrode insertions. When treated with i.p. injection of erythromycin, the myotonia decreased from grade 3 to grade 2 (myotonic discharge in >50% but not full of insertions) or grade 1 (occasional myotonic discharge) (Fig. 4B).

In addition to systemic delivery, oral administration of erythromycin is widely used for human diseases. Continuous oral administration rather than periodic systemic administration is more convenient for patients and is feasible for the treatment of chronic progressive diseases such as DM1. Therefore, we next studied the effect of oral erythromycin administration in the HSA1LR mice. Short-term high-dose per oral (p.o.) erythromycin treatment (300, 600, or 900 mg/kg per day for 5 days) rescued missplicing of Clcn1, Atp2a1, and other events (Bin1, Cacna1s, Cramk2b, Ryr1, Nfix, and Ldb3) similar to i.p. injection (Fig. 5A and Fig. S2). The myotonia in treated mice was also decreased from grade 3 to grade 2 (Fig. 5B). To verify that erythromycin did not affect the transcription of toxic RNA, we assessed the expression of the transgene (HSA) containing expanded CUG repeats by qPCR. Similar to the C2C12 cell model, the expression level of toxic RNA in the HSA1LR mice was not changed by erythromycin treatment (Fig. 5C).
suggesting that erythromycin blocks binding between CUGexp and MBNL1 in vivo. Then, to determine whether erythromycin is effective at the dosage used in humans, we tested low-dose long-term treatment (50 or 100 mg/kg per day p.o. erythromycin for 21 days) in the HSA LR mice. The 50-mg/kg per day treatment group showed a modest but statistically significant (P = 0.006) improvement in Clcn1 splicing relative to saline-injected

Figure 4. Intraperitoneal injection of erythromycin improves splicing defects in Clcn1 and Atp2a1 in a DM1 mouse model. (A) Analysis of Clcn1 (left) and Atp2a1 (right) alternative splicing by RT-PCR in mice treated with intraperitoneal injection of erythromycin (50 or 150 mg/kg for 8 days; n = 6 for experimental, control, and wild type). *P < 0.01. Error bars indicate SEM. (B) Electromyographic myotonia analysis in HSA LR mice treated with intraperitoneal erythromycin. Discussion

DM1 is a slowly progressive, multisystemic disorder for which no curative treatment presently exists. Previous studies identified several small molecules that specifically bind CUG repeats and neutralize the toxic RNA.\(^{17-20}\) Some of these molecules partially rescued missplicing events in DM1 model mice. However, the toxicity and tolerability of these compounds have not been determined in humans, precluding their clinical use in the near future. Drug repositioning is the application of established drugs to new indications and represents a promising way to speed up the development of treatments by capitalizing on existing data and experience.\(^{32}\) The drug-repositioning screen conducted in this study revealed that erythromycin binds CUG\(^{\text{exp}}\) and competitively releases sequestered MBNL1, thereby inducing dispersal of RNA foci and reversing missplicing events in vitro models of DM1. Furthermore, erythromycin administered either orally or systemically rescued missplicing and improved myotonia in the DM1 model mice. Erythromycin has long been a widely used antibiotic. Erythromycin binds to the 50S ribosomal subunit, inhibiting bacterial protein synthesis by blocking the polypeptide exit tunnel.\(^{33}\) In addition to interacting with prokaryotic rRNA, our study demonstrates that erythromycin has a surprisingly high affinity for CUG repeat RNA. Erythromycin also has an anti-inflammatory effect on the respiratory tract, and low-dose long-term oral erythromycin treatment has already been well established in chronic obstructive pulmonary disease (COPD) with excellent tolerability.\(^ {31}\) Because a constant, steady-state level of a therapeutic agent could provide continual inhibition of CUG\(^{\text{exp}}\)-MBNL1 interactions, long-term oral administration of erythromycin would be a more relevant and convenient therapy for DM1 rather than periodic parenteral injections. Indeed, we observed a significant splicing correction in the DM1 model mice with administration of the dose of erythromycin approved for human use (50 or 100 mg/kg per day, p.o.). This is an encouraging result indicating future clinical trials of DM1, because the dose given to mice for long-term oral erythromycin ethylsuccinate treatment would equate to \(-10\) mg/kg per day for human adults, based on mouse-to-human equivalence calculations,\(^ {34}\) which is within the recommended dose range for COPD patients.

Erythromycin is also reported to stimulate gastrointestinal motor activity via effects on motilin receptors.\(^ {35}\) In a previous study, the erythromycin ethylsuccinate
ester was tested to improve gastric emptying in DM1 patients when administered at a dose of 50–200 mg/day for 4 weeks.36 While no significant change in the gastric emptying rate was observed in the study, some gastrointestinal symptoms, including nausea, ability to eat, and diarrhea, were attenuated in DM1 patients. Although the dosage of erythromycin was relatively low and skeletal muscle symptoms were not evaluated, such improvements might have occurred through neutralization of toxic RNA. Interestingly, our in vitro study indicated that erythromycin binding to CUG repeats depends on whether it is in the salt or ester form. In fluorescence titration assays, erythromycin lactobionate showed the highest affinity to CUGexp of the erythromycin derivatives. Although per oral erythromycin ethylsuccinate ester significantly improved Clcn1 and Atp2a1 missplicing in the DM1 model mice, the effect was less than that of the lactobionate form. Because the lactobionate form is currently approved only for intravenous use, encapsulation or lipid-coating will be required for per oral use, as previously attempted in humans.37,38

Erythromycin has been shown to induce QT-interval prolongation in some patients by blocking delayed-rectifier potassium channels.39 Cardiac conduction abnormalities are critical symptoms in DM1, sometimes leading to sudden death.40 Although the major manifestation is prolongation of the PR interval and QRS duration, several studies report a prolonged QT interval in DM1.41 Therefore, careful consideration of the indication for treatment and cautious observation are required for administration of erythromycin in DM1 patients.

Our study revealed erythromycin as the first FDA-approved small molecule that improves the splicing abnormality in DM1 at the usual dose for human use. In addition to its potential for combination therapy with antisense oligonucleotides that degrade the toxic RNA, erythromycin treatment has distinct clinical advantages, as it is effective by oral administration, inexpensive, and remarkably safe as indicated over its long history of use for the treatment of infections and pulmonary diseases.31,42 Our results indicate promising prospects for future DM1 therapy, using erythromycin. Furthermore, the availability of detailed information regarding erythromycin safety hastens clinical trial readiness.
